(54) Title: AN APPARATUS FOR HOLDING A SEMICONDUCTOR WAFER

## (57) Abstract

An apparatus for holding a plurality of semi-conductor wafers during heat treatment of the wafers in a furnace comprises a plurality of rails extending essentially vertically between a top and bottom plate. Each rail contains a plurality of teeth arranged such that the space between adjacent teeth can receive a portion of a single semiconductor wafer. Each tooth contains a raised support structure, typically a ledge, located on the top surface of each tooth for supporting the wafer, usually from the edge of the wafer inward to a point located from the center of the wafer a distance equal to between about 25 % and about 75 % of the wafer's radius. Such an apparatus with its relatively long teeth is especially designed to uniformly support larger wafers, i.e., wafers having a nominal diameter greater than about 200 millimeters, such that their own weight does not cause the wafers to sag and thereby produce crystal dislocations or slip when the wafers are heated to high temperatures.

## AN APPARATUS FOR HOLDING A SEMICONDUCTOR WAFER

BACKGROUND OF INVENTION

5 This invention relates generally to vertical carriers  
or boats for holding semiconductor wafers during heat  
processing and is particularly concerned with a vertical  
carrier designed to effectively support large semiconductor  
wafers having nominal diameters equal to  
10 or greater than about 200 millimeters, preferably wafers having  
nominal diameters of about 300 millimeters or greater.

Semiconductor wafers, especially those made  
of silicon, may be conventionally processed by placing them  
horizontally into a holding device or carrier at intervals in  
the vertical direction and exposing the wafer's surfaces to  
15 high temperature gases in a furnace, usually to form an oxide  
film on these surfaces or to deposit certain atoms therein. To  
maximize the amount of surface area exposed to the heat  
treatment, the wafers are usually held in "boats" or carriers  
typically comprised of parallel vertical supports or rails  
20 having relatively short slots evenly spaced along their length.

The slots in one support are normally aligned with slots in  
the other support so a wafer can be jointly received by a  
corresponding slot in each support. By placing wafers in  
appropriate slots on the supports, the boat can carry a stack  
25 of wafers separated from each other so that both sides of the  
wafer are exposed to the heat treatment.

In the past, conventional vertical boats and carriers  
have been designed to support wafers having nominal diameters  
of 200 millimeters or less. These size wafers are typically  
30 supported by slots on the vertical rails that extend inward  
around the edge of the wafer only a very short distance,  
usually less than about 20 millimeters. Unfortunately, when  
such a design is utilized to support larger wafers, i.e.,  
wafers having a

nominal diameter greater than about 200 millimeters, the wafers are deflected by their own weight and tend to sag. As the temperature in the furnace rises, this sagging or deformation results in crystal dislocation or "slip" and other stresses on the wafer. Although "slip" typically begins to occur at about 1200° C. for wafers having nominal diameters of 200 millimeters, it probably occurs at a temperature of 1000° C. or less for wafers having diameters of 300 millimeters or larger. Crystal dislocations caused by stresses on the wafers result in a decrease in the number of chips that can be made on a wafer. This reduction in product yield increases with wafer size, and therefore the processing of larger wafers in conventional vertical boats has been generally avoided.

Various techniques have been suggested in an attempt to decrease the bending stress on wafers. One method suggested is to locate the rails or vertical supports of the boat or carrier more toward the front of the carrier where the wafers are loaded. This, however, is difficult because of the need for an unobstructed wafer loading path. Another technique for decreasing bending stress on large wafers is taught in U.S. Patent No. 5,492,229, the disclosure of which patent is incorporated herein by reference in its entirety. This patent teaches the use of relatively long support teeth, i.e., the support arms formed by long slits or slots on the support rail, with small contact pads located at or near the end of the teeth for supporting the wafers toward their center and not at their edges. According to this patent, the contact pads or support projections are located such that the inner portion of each wafer is supported by the pad while the peripheral portion, i.e., the portion of the wafer which extends from the edge of the wafer inward a distance of up to 10% of the wafer's radius, does not contact the pads or arms. By supporting the wafers at their inner portion, this design not only reduces the stress on the wafer caused by its own weight

but also decreases heat stress caused by direct heat transfer to the wafer from the slits in the vertical supports.

Although the above-discussed patent proposes the use of long support arms or teeth in order to decrease stress on the wafer, the wafer support is far from uniform as it relies on small contact pads located at or near the end of the support arms, which pads occupy only a small portion of the length of the support arm and contact only a small area of each wafer. Moreover, the design shown in the patent results in reduced tooth strength caused by the removal of material from the top of the tooth to form the small support pads or projections.

#### SUMMARY OF THE INVENTION

In accordance with the invention, it has now been found that more uniform support for large semiconductor wafers can be achieved in vertical wafer carriers by using long teeth or support arms containing a raised support structure that typically extends along each tooth a distance greater than about 50%, preferably greater than about 70%, of the tooth's length in such a manner as to provide support for each wafer from a point located inward from the edge of the wafer a distance equal to less than about 9% of the wafer's radius to a point located from the center of the wafer a distance equal to between about 25% and about 80% of the wafer's radius. Such teeth and their associated support structures can provide essentially continuous support from the wafer periphery inward and effectively reduce stress induced by the wafer's own weight. Moreover, by utilizing a support structure integral with each tooth that extends from the front tip of a tooth to near its back end, the strength of each individual tooth is increased.

Typically, the wafer carriers of the invention effectively support semiconductor wafers having diameters between about 195 and about 410 millimeters utilizing three or

more support rails which extend vertically between a top portion and a bottom portion of the carrier. The raised structure which supports the wafers generally runs from the tip of a tooth continuously toward the back and has a surface area  
5 between about 20 and about 200 square millimeters when supporting wafers having nominal diameters between about 200 and about 400 millimeters. Typically, the support structure is a ledge which runs along one side of each tooth and continuously supports the wafer from the edge of the wafer to a  
10 point located from the center of the wafer between about 40% and about 65% of the wafer's radius.

The use of a structure that extends over about 50% of the length of a tooth to support a wafer, as opposed to a support projection or pad as disclosed in U.S. Patent No.  
15 5,492,229, results in more effective and uniform support for the wafer and thereby more effectively decreases the stress on the wafer caused by its own weight. In addition, such a support structure, when integral with each tooth, provides increased strength to the teeth of the carrier.

#### BRIEF DESCRIPTION OF THE DRAWINGS

Figure 1 in the drawings is a partial perspective view of a preferred embodiment of a semiconductor wafer carrier of the invention with the top portion cut away so that it can  
25 be seen how a hypothetical wafer would be held in the carrier;

Figure 2 is a perspective view of each side of one of the vertical support members or rails shown in Figure 1;

Figure 3 is a top view of the portion of the wafer carrier shown in Figure 1;

Figure 4 is a perspective view of each side of a vertical support member or rail just prior to the support ledges being formed at the side of each tooth;

Figure 5 is a perspective view of each side of a  
35 vertical support member or rail just prior to a series

of interrupted or spaced pads being formed at the side of each tooth; and

Figure 6 is a perspective view of each side of a silicon carbide vertical support member or rail after a series of interrupted or spaced pads have been formed at the side of each tooth.

All identical reference numerals in the figures of the drawings refer to the same or similar elements or features.

#### DETAILED DESCRIPTION OF THE INVENTION

Figures 1 and 3 in the drawings show a preferred embodiment of a semiconductor wafer carrier 11 of the invention. The carrier comprises a bottom portion or plate 10 on which are mounted four vertical supports or rails 12 and 14 which extend upward between the bottom plate and a top portion or plate not shown in the figures. The two rails 12 located on the left side of the carrier, i.e., to the left of the centerline 20 of plate 10, are identical and are mirror images of the two rails 14 located on the right side of the carrier, i.e., to the right of centerline 20. The two rails 14 are identical with each other and are mirror images of rails 12. Perspective views illustrating the details of each side of a rail 14 is shown in Figure 2. Generally, the design of the bottom plate 10 and top plate is dependent on the type of apparatus used to move the carrier in and out of the furnace where the wafers are to be heat treated and the design of the furnace itself.

For purposes of illustrating and explaining the invention, a wafer 16 is shown in Figure 1 as a dotted line in its appropriate position after being inserted into the wafer carrier 11. Generally, the design of the wafer carrier depends upon the size of the wafers to be held and supported. Typically, the nominal diameter of the wafers held in the carrier ranges from about 200 to about 400 millimeters, although other diameter wafers can be accommodated if desired. Such

wafers usually have a thickness which ranges from about 0.5 to about 1.5 millimeters.

Each support rail 12 and 14 contains a plurality of support arms or teeth 24 and 26, respectively, which in turn define slots 28 into which the semiconductor wafers are inserted. The slots are aligned so that a single wafer can be jointly received by a corresponding slot in each rail, thereby allowing the carrier to hold wafers in a stack. Each tooth 24 and 26 contains a ledge 30 which runs along a side of the tooth from its front tip 32 toward its back edge 34. The ledge serves to support a wafer, normally from the edge of the wafer inward toward a centerline 18 or 20 of the wafer as illustrated in Figure 3.

The long support teeth 24 and 26 are created in rails 12 and 14, respectively, by machining slots 28 into the rails.

Although the rails shown in Figures 1-3 are plate-like members in an L-shape, the rails can have other shapes. For example, they may have U-shaped or C-shaped cross sections. The actual length of the rails is dependent upon the height of the furnace in which the semiconductor wafers are to be treated. Typically, the rails will vary in length between about 0.5 and about 1.5 meters, but are usually somewhere between about 0.6 and about 1.0 meter in length.

Although Figures 1 and 3 show that there are four support rails in the wafer carrier of the invention, it will be understood that carriers containing two or three rails are within the scope of the invention. Although three or four support rails are normally optimum from a point of view of support and cost of fabrication of the wafer carrier, more rails may be used if desired.

As can be seen from Figures 1 and 3, rails 12 are attached to and located on the left side (to the left of centerline 20) of bottom plate 10, whereas rails 14 are located on the right side (to the right of centerline 20). Ideally, for the most uniform support of wafers, the four rails should be equally spaced, i.e., about 90°, from

each other in a circle on the bottom plate. Unfortunately, such an arrangement does not permit placement of the wafers into the carrier. In order for there to be sufficient clearance to load the wafers into the front of the wafer carrier, each rail 12 and 14 located in front of centerline 18 of plate 10 normally must be spaced between about 150° and about 175° from each other when measured the short way around bottom plate 10. When it is desired to utilize only three rails for support, two of the rails are located toward the front of the wafer carrier as shown in Figures 1 and 3 while one rail is located at the back of the carrier, normally on the centerline 20 of the bottom plate. Typically, the front rails support between about 55 percent and about 90 percent of the weight of each wafer.

The number of slots 28 in each rail 12 and 14 depends upon the number of semiconductor wafers to be held by the wafer carrier. This, in turn, depends upon the size of the furnace to be used for heat treatment and the separation desired between wafers to adequately expose both the top and bottom surfaces of the wafers to the heat treatment. Normally, each rail contains between about 50 and about 240 slots. For a typical larger size furnace, the number of slots normally ranges between about 80 and about 150.

The teeth 24 and 26 of rails 12 and 14, respectively, are formed when the slots are cut into the rails. The shape of the teeth typically depends upon the shape of the plate-like member from which the rails are fabricated. Although the teeth 24 and 26 as shown in Figures 1 through 3 are wedge-shaped, i.e., they taper outwardly from their front tip 32 toward their back end 34, the teeth can also be in the shape of a long rectangle or curved as is an arc of a circle. Generally, when the teeth are straight, they range in length between about 20% to about 80% of the semiconductor wafer's radius, preferably between about 40% and about 60%. Normally, the

teeth are between about 20 and about 150 millimeters long, preferably about 50 to about 100 millimeters.

Each tooth on a rail contains a support structure or ledge 30 which runs usually continuously along one side of the tooth from the front tip of the tooth 32 toward the back end of the tooth 34 a distance equal to at least about 70%, usually at least about 80%, of the length of the tooth. The ledge provides support for the semiconductor wafer which is received in the slot between two teeth. The support structure or ledge is designed to provide support for the wafer usually from the edge of the wafer inward to a point located from the center of the wafer a distance equal to between about 25% and about 80%, preferably between about 45% and about 60%, of the wafer's radius. Although it is preferred that the ledge support the wafer beginning at its edge inward, the actual support may begin as far as about 9% of the wafer's radius from the edge of the wafer, more preferably less than about 5% of the wafer's radius from the edge of the wafer.

Although support structure or ledge 30 is normally designed to provide continuous support to a wafer from its edge inward, it is preferable that the contact area with the underside of the wafer be as small as possible in order to expose the maximum amount of wafer surface area to the heat treating process and to reduce heat transfer by thermal conductivity to the bottom of the wafer, which heat transfer will cause nonuniform expansion and stress on the wafer. Of course, the actual surface area of the top of the support structure 30 will depend upon the size of the tooth, which in turn depends upon the size of the wafer to be supported. Typically, for a wafer having a nominal diameter between about 200 and about 400 millimeters, the surface area of the top of the support structure will range between about 20 and about 200 square millimeters, preferably between about 30 and about 120 square millimeters.

The height of the support structure 30 is normally sufficient to allow gases in the furnace to

access the area between the top surface of teeth 24 and 26, represented respectively by reference numerals 36 and 38 in Figure 3, and the underside of each wafer. Typically, the  
5 height ranges between about 0.25 and about 2.5 millimeters, preferably between about 0.5 and about 1.25 millimeters. The distance between the top of the support structure or ledge and the bottom surface of the next higher adjacent tooth usually ranges between about 0.75 and about 4.0 millimeters, preferably  
10 between about 1.5 and about 3.0 millimeters.

Although the support structure 30 shown in Figures 1 through 3 is in the shape of a ledge running along a side of each tooth from its tip 32 substantially continuously toward its back edge 34, it will be understood that the wafer carrier  
15 of the invention is not limited to having support structures in this shape or location. For example, the support structure may be a ledge that runs down the center of the tooth, a narrow lip along the edges of the tooth, a line-like contact along the center of the tooth, a series of short, interrupted pads  
20 running along the edges of the tooth or down the middle of the tooth, or some other means for support. Regardless of the shape the support structure takes or its location, it is important that it provide support for the underside of a semiconductor wafer from a point located within a distance  
25 equal to about 9% of the wafer's radius from the edge of the wafer inward to a point located from the center of the wafer a distance between about 25% and about 80% of the wafer's radius.

Although it is preferred that the support be structurally continuous as is the support ledge shown in the figures, a  
30 discontinuous support structure, such as series of pads, will suffice if it provides support over the specified distance and occupies more than about 50% of the length of a tooth.

It has been found that, when the support structure supplies support to each wafer beginning at a point near the  
35 edge of the wafer and continuing inward,

stress caused by the wafer's weight is substantially reduced as compared to when support is supplied only at the inner portion of the wafer. Moreover, utilizing a support structure which is integral with and occupies at least about 50% of the length of each tooth increases the strength of each individual tooth.

As illustrated in Figure 1, wafer carrier 11 of the invention is comprised of bottom plate 10, rails 12 and 14, and a top plate not shown. Usually, the top and bottom plates and the rails are all made of the same high strength and high purity ceramic material, which is normally substantially resistant to chemical corrosion and has a high heat resistance.

Examples of such ceramic materials include quartz, carbon, graphite, monocrystal silicon, polycrystal silicon, silicon carbide, and silicon carbide impregnated with silicon.

As mentioned previously, the teeth of the rails are usually formed by machining slots 28 into the rails. Thus, the teeth and the rails form a monolithic or unibody structure in which the teeth and rails are integral with each other.

Although it is possible that the raised support structures could be added to the teeth after they are cut from the rails, it is preferred that the support structures also be cut from the rails with the teeth so that they form a monolithic structure with the rails and teeth. Thus, in fabricating the wafer carrier of the invention, slots are machined into the rails to form the teeth with the appropriate support structures integral therewith, and the rails are then attached to the bottom and top plates.

When a relatively soft ceramic material, such as graphite, is used to fabricate the wafer carrier of the invention, conventional precision cutting machines may be used to cut the slots in the rails. It is preferred, however, that the wafer carrier be made of silicon carbide, which is a very strong and hard ceramic material that more easily withstands the harsh environment of the heat treatment furnaces in which the

semiconductor wafers are processed. Unfortunately, it is very difficult to machine teeth and their associated support structures of desired dimensions into rails made of silicon carbide with the accuracy required by the semiconductor manufacturers that use wafer carriers. It has now been found that, in fabricating wafer carriers of the invention made of silicon carbide, it is much easier to first machine the teeth into rails made of the softer graphite, convert the graphite to silicon carbide, and then carry out any final cutting or grinding needed to produce teeth and support structures to exact specifications.

The first step in fabricating a silicon carbide wafer carrier of the invention is to cut a plate of graphite, preferably one having a cross-section in a L-shaped wedge as shown in Figure 3, from a block of graphite. Graphite is then removed from the plate, normally using an endmill, to form a first series of parallel grooves or slots 28 but leaving a "back" wall 40 intact as shown in Figure 4 for a rail 14 to be used on the right side of the carrier. Normally, the slots are cut into the plate to a depth such that back wall 40 is not penetrated and is between about 1/4 and about 6 millimeters, preferably between about 1/2 and about 3 millimeters, thick. Rails 12 to be used on the left side of the wafer carrier are then fabricated out of graphite in the same manner. These partially fabricated graphite rails and the graphite bottom and top plates, which are also cut from graphite blocks in the desired design, are then converted into silicon carbide by heating them to high temperatures in a furnace in the presence of silica and carbon. At the elevated temperatures in the furnace, the silica reacts with carbon to form silicon monoxide which then reacts with the carbon in the graphite to form silicon carbide. This method of converting graphite into silicon carbide is described in more detail in U.S. Patent Nos. 1,013,700 and 3,634,116, the disclosures

of which are incorporated herein by reference in their entireties.

Once the rails and top and bottom plates have been converted to silicon carbide, slots of a width smaller than those cut in the graphite are ground into the "back" wall 40 remaining on rails 14 and 12. Typically, these slots are ground into the wall with conventional silicon carbide grinding equipment, such as computer numeric controlled grinders equipped with diamond wheels, between the bottom surface of one tooth 26 and the top surface of the next adjacent tooth, thereby forming support ledges 30 as shown in Figure 2. Although Figure 2 does not show ledges similar to ledge 30 on the bottom of each tooth, such ledges will very often be present due to the manufacturing technique used to make the silicon carbide rails. Once the slots are cut to form the ledges, the wafer carrier is assembled by connecting the rails to the bottom and top plates normally using graphite cement. The assembled wafer carrier is then subjected to the silicon carbide conversion process described above in order to convert the graphite cement into silicon carbide, thus forming the silicon carbide wafer carrier.

In the above-described embodiment of the invention, the fabricated silicon carbide rails comprise teeth that have a support structure in the form of a continuous ledge running along one side of each tooth. In an alternative embodiment of the invention, the support structure is a series of short interrupted pads that run along one side of each tooth. Such rails are fabricated in a somewhat similar manner as described above for making rails having continuous ledges but differ in that the back wall 40 of the graphite plate is penetrated in such a manner as to form a series of parallel interrupted slots 42 as shown in Figure 5. These slots connect with the slots 28 cut into the plate from its front side. The interrupted slots, which normally have a width equal to that of the parallel slots

28, can be cut into the back wall of the graphite plate either before, after or at the same time that the parallel slots 28 are cut into the front side of the graphite plate.

5           Once the interrupted slots 42 have been cut into the back side wall 40 of the graphite plate, the plate is converted to silicon carbide as described above. The interrupted pads 44 shown in Figure 6, which figure depicts a finished silicon carbide rail 14 of the in-  
10           vention, are then formed by using conventional silicon carbide grinding equipment to connect horizontally adjacent slots 42 shown in Figure 5 with each other on the back side wall 40. This is accomplished by grinding a series of grooves or slots of a width smaller than that  
15           of slots 28 into the back side wall 40 of the silicon carbide plate between the bottom surface of one tooth 26 and the top surface of the next adjacent tooth, thereby forming the series of interrupted pads 44 on each tooth. Although Figure 6 does not show interrupted pads similar  
20           to the pads 44 on the bottom of each tooth, such pads will very often be present due to the manufacturing technique used to make the silicon carbide rails. Once these silicon carbide rails are fabricated, they are assembled to form a wafer carrier of the invention as  
25           described previously.

          The length of the support pads 44 shown in Figure 6 is determined by the distance between horizontally adjacent slots 42. Usually, this distance is set so the pads have a length between about 2 and about 30  
30           millimeters, preferably between about 3 and about 12 millimeters.

          The method of the invention as described above has several advantages when used to manufacture silicon carbide rails or supports for use in vertical carriers  
35           designed to hold large wafers. First, by machining the major portion of the slots which form the rail teeth in softer graphite, the amount of silicon carbide that has to be machined is greatly reduced. This results in less

incidences of tooth and rail breakage and a lower manufacturing scrap rate. Second, since smaller amounts of silicon carbide need to be machined, the support structures can be more precisely ground to meet required  
5 final tolerances.

Although this invention has been described by reference to several embodiments of the invention, it is evident that many alterations, modifications and variations will be apparent to those skilled in the art in  
10 light of the foregoing description. Accordingly, it is intended to embrace within the invention all such alternatives, modifications and variations that fall within the spirit and scope of the appended claims.

I CLAIM

1. An apparatus for holding a plurality of semiconductor wafers, said apparatus comprising:

(a) a top portion and a bottom portion;

5 (b) a plurality of rails extending between said top and bottom portions;

(c) a plurality of teeth on said rails, wherein the space between the top surface of one tooth and the bottom surface of the next higher adjacent tooth forms a slot for receiving a portion of a single semiconductor wafer; and

10 (d) a raised support structure for contacting and supporting said single semiconductor wafer located on the top surface of substantially all teeth that form the bottom of a slot, said raised support structure providing support for said wafer from the edge of said wafer, or from a point located  
15 inward from the edge of said wafer a distance equal to less than 9.0% of the radius of said wafer, to a point located from the center of said wafer a distance equal to between about 25% and about 80% of the radius of said wafer.

2. The apparatus as defined by claim 1 wherein the length of said teeth is between about 20% and about 80% of the radius of said wafers.

3. The apparatus as defined by claim 1 wherein said raised support structure provides support for said single semiconductor wafer from the edge of said wafer or from a point located inward from the edge of said wafer a distance equal to  
5 less than about 5.0% of the radius of said wafer.

4. The apparatus as defined by claim 1 wherein each rail contains between about 50 and about 240 slots.

5. The apparatus as defined by claim 1 wherein said raised support structure provides support for said single semiconductor wafer from the edge of said wafer.

6. The apparatus as defined by claim 1 wherein said rails are between about 0.5 and about 1.5 meters in length.

7. The apparatus as defined by claim 1 wherein said teeth taper outwardly from their front tip to their back edge.

8. The apparatus as defined by claim 1 wherein the distance between the top of said raised support structure and the bottom surface of the next higher adjacent tooth is between about 0.75 and about 4.0 millimeters.

9. The apparatus as defined by claim 1 made of silicon carbide.

10. The apparatus as defined by claim 1 wherein each rail, its teeth and their raised support structures form a monolithic structure.

11. The apparatus as defined by claim 1 wherein the surface area of the top of said raised support structure is between about 20 and about 200 square millimeters.

12. The apparatus as defined by claim 11 wherein said raised support structure is a ledge running along one side of a tooth.

13. The apparatus as defined by claim 12 wherein said ledge continuously contacts and supports said single semiconductor wafer from the edge of said wafer to a point located from the center of said wafer a distance equal to between about 40% and about 60% of said wafer's radius.

14. The apparatus as defined by claim 3 wherein said raised support structure occupies greater than about 70% of the length of each tooth.

15. The apparatus as defined by claim 13 wherein said ledge is between about 0.25 and about 2.5 millimeters in height.

16. The apparatus as defined by claim 1 containing three rails, two of which are located on the front side of said apparatus where said plurality of semiconductor wafers are inserted into said slots and one  
5 which is located on the back side of said apparatus.

17. The apparatus as defined by claim 1 containing four rails, two of which are located on the front side of said apparatus where said plurality of semiconductor wafers are inserted into said slots and two  
5 of which are located on the back side of said apparatus.

18. The apparatus as defined by claim 1 wherein the surface area of the top of said raised support structure is between about 30 and about 120 square millimeters.

19. An apparatus for holding a plurality of semiconductor wafers having nominal diameters of 200 millimeters or greater, said apparatus comprising:

- 5 (a) a top plate and bottom plate;
- (b) at least three rails extending essentially vertically between said top and bottom plates;
- (c) a plurality of substantially horizontal teeth formed on said rails, wherein the space between the top surface of one tooth and the bottom surface of the  
10 next higher adjacent tooth forms a slot for receiving a portion of a single semiconductor wafer; and
- (d) a raised support structure for contacting and supporting said single semiconductor wafer located on the top surface of substantially all teeth that form the

10 bottom of a slot, said raised support structure providing  
support for said wafer from the edge of said wafer to a point  
located from the center of said wafer a distance equal to  
between about 40% and about 65% of the radius of said wafer,  
wherein each rail, its teeth and their raised support  
15 structures form a monolithic structure.

20. The apparatus as defined by claim 19 wherein said  
apparatus is made of silicon carbide.

21. The apparatus as defined by claim 19 wherein said  
raised support structure is a ledge running along one side of a  
tooth.

22. The apparatus as defined by claim 21 wherein said  
raised support structure occupies greater than about 70% of the  
length of each tooth.

23. The apparatus as defined by claim 22 containing  
four rails.

24. The apparatus as defined by claim 22 wherein said  
plurality of semiconductor wafers have a nominal diameter of  
about 300 millimeters.

25. A rail for use as a support in an apparatus for  
holding a plurality of semiconductor wafers, which rail  
comprises:

5 (a) a plurality of teeth arranged such that the space  
between the top surface of one tooth and the bottom surface of  
the next higher adjacent tooth forms a slot for receiving a  
portion of a semiconductor wafer, wherein the length of each  
tooth is greater than about 20 millimeters; and

(b) a raised support structure for contacting and  
supporting said wafer located on the top surface of  
substantially all teeth that form the bottom of a slot,

said raised support structure occupying greater than about 50% of the length of each tooth.

26. The rail as defined by claim 25 wherein the length of each tooth is greater than about 25 millimeters.

27. The rail as defined by claim 25 wherein the length of each tooth is between about 30 and about 100 millimeters.

28. The rail as defined by claim 27 wherein said raised support structure occupies greater than about 70% of the length of each tooth.

29. The rail as defined by claim 28 wherein said raised support structure is a ledge running along one side of a tooth.

30. The rail as defined by claim 29 wherein said ledge runs continuously from the front tip of said tooth to a point located on said tooth at least about 80% of the length of the tooth from said tip of said tooth.

31. The rail as defined by claim 30 wherein the surface area of the top of said ledge is between about 30 and about 120 square millimeters.

32. The rail as defined by claim 31 composed of silicon carbide.

33. The rail as defined by claim 32 in the form of a monolithic structure.

34. A method for making a silicon carbide rail for use as a support in an apparatus for holding a plurality of semiconductor wafers, which method comprises:

(a) forming a series of first parallel slots into a solid plate of graphite having a front side and a back side, wherein each of said slots extends from said front side toward said back side, thereby forming a back side wall;

5 (b) converting said graphite plate into silicon carbide to form a slotted silicon carbide plate; and

10 (c) forming a series of second parallel slots having a width less than the width of slots in said first series in said back side wall of said slotted silicon carbide plate such that each of said slots in said second series connects with each of said slots in said first series to form teeth having a ledge running along their top surfaces.

35. The method as defined by claim 34 wherein said second series of slots are ground into the back side wall of said silicon carbide plate.

36. The method as defined by claim 34 wherein said slots extend from said front side toward said back side a distance such that said back side wall is between about 1/4 and about 6 millimeters thick.

37. The method as defined by claim 34 wherein said first series of parallel slots do not penetrate said back side wall.

38. A method for making a silicon carbide rail for use as a support in an apparatus for holding a plurality of semiconductor wafers, which method comprises:

5 (a) forming a series of first parallel slots into a solid plate of graphite having a front side and a back side, wherein each of said slots extends from said front side toward said back side, thereby forming a back side wall;

(b) forming a series of parallel interrupted slots in said back side wall such that each series of interrupted slots connects with a slot in said first series of parallel slots;

(c) converting said graphite plate into silicon carbide to form a slotted silicon carbide plate; and

(d) forming a series of parallel grooves having a width smaller than that of said first series of parallel slots in said back side wall to connect horizontally adjacent interrupted slot with each other and thereby form teeth having a series of pads running along their top surfaces.

39. An apparatus for holding a semiconductor wafer, said apparatus comprising:

(a) a top portion and a bottom portion;

(b) a rail extending between said top and bottom portions;

(c) a plurality of teeth on the rail; and

(d) a raised support structure for contacting or supporting the semiconductor wafer.

40. An apparatus for holding a semiconductor wafer, said apparatus comprising:

(a) a top plate and bottom plate;

(b) a rail extending between said top and bottom plates;

(c) a plurality of teeth formed on the rail; and

(d) a raised support structure for contacting or supporting the semiconductor wafer.

41. A rail for use as a support in an apparatus for holding a semiconductor wafer, which rail comprises:

(a) a plurality of teeth; and

(b) a raised support structure for contacting or supporting the wafer.

42. A method for making a rail for use as a support in an apparatus for holding a semiconductor wafer, which method comprises:

- (a) forming a series of first slots into a plate;
- (b) converting the plate into silicon carbide to form a slotted silicon carbide plate; and
- (c) forming a series of second slots in the slotted silicon carbide plate.

43. A method for making a rail for use as a support in an apparatus for holding a semiconductor wafer, which method comprises:

- (a) forming a series of first slots into a plate;
- (b) forming a second series of slots in the plate;
- (c) converting the plate into silicon carbide to form a slotted silicon carbide plate; and
- (d) forming a series of grooves in the plate.

# INTERNATIONAL SEARCH REPORT

Int'l Application No  
PCT/US 99/21554

## A. CLASSIFICATION OF SUBJECT MATTER

IPC 7 H01L21/00

According to International Patent Classification (IPC) or to both national classification and IPC

## B. FIELDS SEARCHED

Minimum documentation searched (classification system followed by classification symbols)

IPC 7 H01L

Documentation searched other than minimum documentation to the extent that such documents are included in the fields searched

Electronic data base consulted during the international search (name of data base and, where practical, search terms used)

## C. DOCUMENTS CONSIDERED TO BE RELEVANT

Category *	Citation of document, with indication, where appropriate, of the relevant passages	Relevant to claim No.
X	WO 97 32339 A (TOKYO ELECTRON LIMITED) 4 September 1997 (1997-09-04)	1-6, 9, 10, 16, 17, 19, 20, 25-27, 39-41

### \* Special categories of cited documents:

"A" document defining the general state of the art which is not considered to be of particular relevance

"E" earlier document but published on or after the international filing date

"L" document which may throw doubts on priority claim(s) or which is cited to establish the publication date of another citation or other special reason (as specified)

"O" document referring to an oral disclosure, use, exhibition or other means

"P" document published prior to the international filing date but later than the priority date claimed

"T" later document published after the international filing date or priority date and not in conflict with the application but cited to understand the principle or theory underlying the invention

"X" document of particular relevance; the claimed invention cannot be considered novel or cannot be considered to involve an inventive step when the document is taken alone

"Y" document of particular relevance; the claimed invention cannot be considered to involve an inventive step when the document is combined with one or more other such documents, such combination being obvious to a person skilled in the art.

"&" document member of the same patent family
